Technical Report #CS-TR-07-03
June 2007

Abstract

We present a divide-and-conquer method, called DiConic, for automatic addition of failsafe fault-tolerance to distributed programs, where a failsafe program guarantees to meet its safety specification even when faults occur. Specifically, instead of adding fault-tolerance to a program as a whole, we separately revise program actions so that the entire program becomes failsafe fault-tolerant. Our DiConic algorithm has the potential to utilize the processing power of a large number of machines working in parallel, thereby enabling automatic addition of failsafe fault-tolerance to distributed programs with a large number of processes. We formulate our DiConic synthesis algorithm in terms of the satisfiability problem and apply it to several case studies using the Yices Satisfiability Modulo Theories (SMT) solver. We demonstrate our DiConic approach for the classic Byzantine Generals problem and an industrial application.

1 Introduction

Software intensive systems are inevitably subject to the occurrence of unanticipated faults as it is difficult (if not impossible) to anticipate all types of faults in early stages of development. Automatic addition of fault-tolerance to programs provides a systematic approach for equipping an existing program with necessary fault-tolerance functionalities while preserving its correctness in the absence of faults. However, the exponential complexity of automatic addition of fault-tolerance to distributed programs [1] urges us to devise new paradigms for the addition of fault-tolerance that scale better than existing techniques. In this paper, we present a Divide-and-CONquer paradigm, called DiConic, that decomposes the problem of automatic addition of failsafe fault-tolerance - where a failsafe program meets its safety specification even when faults occur – into a set of sub-problems, where in each sub-problem, we focus on revising an individual program action (specified in terms of Dijkstra’s guarded command language [2]) in such a way that the entire program becomes failsafe fault-tolerant.

Most existing approaches [3–13] for automated synthesis of fault-tolerant programs generate an integrated combinatorial model of a program (implemented as a reachability graph in enumerative techniques [10–12] or as a set of Binary Decision Diagrams (BDDs) in symbolic methods [8, 13]) which makes it difficult to scale such methods as the size\(^2\) of the program increases. For example, specification-based approaches [3, 9] synthesize the abstract structure of a fault-tolerant program as a finite-state machine from the satisfiability proof of its temporal logic specification. Control-theoretic techniques [5, 7] use synchronous automata-theoretic product to generate finite state automata that represent fault-tolerant discrete-event controllers. Game-theoretic methods [4, 6] synthesize a winning strategy that captures all program behaviors. Previous work on addition of fault-tolerance to concurrent and distributed programs [10–12] takes an integrated model (represented as a finite-state machine) of an existing program and automatically revises the program model in order to generate a model of a fault-tolerant version thereof. Symbolic techniques [8, 13] enable the synthesis of larger programs, however, they still suffer from the complexity of synthesis as they deal with

\(^2\)In this work, we determine the size of the program by the number of its processes, which has a direct relation with the total number of program actions, variables, and state space.
the synthesis problem as a whole without decomposing the problem. While all aforementioned approaches present important and useful techniques for synthesizing fault-tolerant programs and mitigating space/time complexity of addition, we believe that decomposing the synthesis problem so that each sub-problem can be solved separately is equally important and is orthogonal to complexity issues.

In order to decompose the problem of automatic addition of failsafe fault-tolerance, we focus on the following questions: Given a fault-intolerant program that satisfies its specification in the absence of faults, but provides no guarantees in the presence of faults, how can we determine whether or not each program action should be revised so that the entire program becomes fault-tolerant? If indeed a program action should be revised, how do we independently identify the nature of the change for that action? These questions are indeed special cases of a more general question, which is the focus of our research: Given a program that meets its specification and a new desired property raised due to the change in requirements, how do we revise each program action so that the revised program satisfies the new property while preserving its existing specification? To address this question for the addition of failsafe fault-tolerance, we present a sound distributed algorithm that has two components: synthesis coordinator and synthesis node. Corresponding to each program action, we instantiate a synthesis node that determines how that action should be revised towards the synthesis of a failsafe version of the input program. The synthesis coordinator synchronizes the activities of synthesis nodes. There is only one synchronization point between a synthesis node and the synthesis coordinator, which helps decreasing the communication cost of our algorithm. As the number of program actions increases one can instantiate new synthesis nodes and deploy them on different machines in a parallel platform.

Our proposed synthesis algorithm is a distributed fixpoint computation where in each round of the computation synthesis nodes report their results to the synthesis coordinator. More specifically, our algorithm takes a fault-intolerant program (as a set of actions) and a set of fault actions, and instantiates (i) $N$ synthesis nodes, where $N$ is the total number of program and fault actions, and (ii) one coordinator node. Each synthesis node performs a set of verification and revision operations that could be done irrespective of revisions performed on
other actions in other synthesis nodes. Afterwards, each synthesis node reports its revised action to the coordinator node and waits for coordinator’s reply. At the end of each round, the collection of the actions in all synthesis nodes comprises an intermediate program. The coordinator verifies some constraints on the intermediate program and broadcasts the results to all synthesis nodes that are waiting to enter the next round of synthesis. A synthesis node terminates in two possible cases. First, the synthesis node locally determines that its associated action should be removed in the failsafe program. Second, the synthesis node receives a termination message from the coordinator. The coordinator terminates either by finding a failsafe program or by declaring failure.

We have employed the Yices Satisfiability Modulo Theories (SMT) solver [14] (developed at SRI International) to apply our DiConic approach to four case studies among which (i) the classic problem of Byzantine Generals (BG) [15], and (ii) an altitude switch controller program that has been manually designed at the Naval Research Laboratory [16]. The Yices specifications of these case studies are available in the Appendix. The organization of this report is as follows: We present preliminary concepts in Section 2. In Section 3, we represent the problem of adding failsafe fault-tolerance. Subsequently, in Section 4, we reiterate an enumerative solution due to Kulkarni et al. [17] where they add failsafe fault-tolerance to distributed programs represented as finite-state machines. Then, in Section 5, we present our DiConic algorithm. We use the BG problem as a running example to demonstrate our approach. Additionally, in Section 6, we present three case studies for DiConic addition of failsafe fault-tolerance to (i) a simplified version of an altitude switch controller (from [16]), (ii) a cruise control system, and (iii) a token ring protocol. We discuss related work in Section 7. Finally, we make concluding remarks and discuss future work in Section 8.

2 Preliminaries

In this section, we provide formal definitions of programs, problem specifications, faults, and failsafe fault-tolerance. The definition of specifications is adapted from Alpern and Schneider [18]. The definition of programs, faults and fault-tolerance is adapted from Arora and Gouda [19] and Arora and Kulkarni [20]. The issues of modeling distributed programs
is adapted from Attie and Emerson [21], and Kulkarni and Arora [10]. To illustrate our modeling approach, we use the Byzantine Generals (BG) problem [15] as a running example and use sans serif font for the exposition of the BG example.

**Programs and processes.** A program \( p = \langle V_p, \Pi_p \rangle \) is a tuple of a finite set \( V_p \) of variables and a finite set \( \Pi_p \) of processes. Each variable \( v_i \in V_p \), for \( 1 \leq i \leq n \), has a finite non-empty domain \( D_i \). A state \( s \) of a program \( p \) is a valuation \( \langle d_1, d_2, \ldots, d_n \rangle \) of program variables \( \langle v_1, v_2, \ldots, v_n \rangle \), where \( d_i \) is a value in \( D_i \). The state space \( Q_p \) is the set of all possible states of \( p \). A transition of \( p \) is of the form \( (s, s') \), where \( s \) and \( s' \) are program states. A process \( P_j \), \( 1 \leq j \leq k \), includes a finite set of actions. An action is a guarded command (due to Dijkstra [2]) of the form \( g \text{rd} \rightarrow \text{stmt} \), where \( g \text{rd} \) is a Boolean expression specified over \( V_p \) and \( \text{stmt} \) is an assignment that atomically updates zero or more variables. An assignment always terminates once executed. The set of program actions is the union of the actions of all its processes. We represent the new values of updated variables as primed values. For example, if an action updates the value of an integer variable \( v_1 \) from 0 to 1, then we have \( v_1 = 0 \) and \( v'_1 = 1 \).

**BG example.** We consider the canonical version of the Byzantine generals problem [15] where there are 4 distributed processes \( P_g, P_j, P_k, \) and \( P_l \) such that \( P_g \) is the general and \( P_j, P_k, \) and \( P_l \) are the non-generals. (An identical explanation is applicable for arbitrary number of non-generals.) In the fault-intolerant BG program, the general sends its decision to non-generals and subsequently non-generals output their decisions. Thus, each process has a variable \( d \) to represent its decision, a Boolean variable \( b \) to represent if that process is Byzantine, and a variable \( f \) to represent if that process has finalized (output) its decision. A Byzantine process may arbitrarily change its \( d \) and/or \( f \) values. The program variables and their domains are as follows:

\[
\begin{align*}
  d.g & : \{0, 1\} ; \\
  d.j, d.k, d.l & : \{0, 1, \perp\} \quad // \quad \perp \text{ denotes uninitialized decision} \\
  b.g, b.j, b.k, b.l & : \{\text{true, false}\} \quad // \quad b.j = \text{true} \quad \text{iff} \quad P_j \text{ is Byzantine} \\
  f.j, f.k, f.l & : \{\text{false, true}\} \quad // \quad f.j = \text{true} \quad \text{iff} \quad P_j \text{ has finalized its decision}
\end{align*}
\]

We represent the actions of the non-general process \( P_j \) as follows. We label these actions with \( BG_1 \) and \( BG_2 \). (The actions of other non-generals are similar.)

\[
\begin{align*}
  BG_1 : \quad d.j = \perp \land \neg f.j & \quad \rightarrow \quad d.j := d.g; \\
  BG_2 : \quad d.j \neq \perp \land \neg f.j & \quad \rightarrow \quad f.j := \text{true};
\end{align*}
\]
A non-general process that has not yet decided copies the decision of the general. When a non-general process decides, it can finalize its decision.

**State and transition predicates.** A state predicate of \( p \) is a subset of \( Q_p \) specified as a Boolean expression over \( V_p \). An unprimed state predicate is specified only in terms of unprimed variables. Likewise, a primed state predicate includes only primed variables. A transition predicate (adapted from [22, 23]) is a subset of \( Q_p \times Q_p \) represented as a Boolean expression over both unprimed and primed variables. We say a state predicate \( X \) holds at a state \( s \) (respectively, \( s \in X \)) if and only if (iff) \( X \) evaluates to true at \( s \). Note that, a state predicate \( X \) also represents a transition predicate that includes all transitions \((s, s')\), where either \( s \in X \) and \( s' \) is an arbitrary state, or \( s \) is an arbitrary state and \( s' \in X \). An action \( grd \rightarrow stmt \) is enabled at a state \( s \) iff \( grd \) holds at \( s \). A process \( P_j \in \Pi_p \) is enabled at \( s \) iff there exists an action of \( P_j \) that is enabled at \( s \). We define a function \( Primed \) (respectively, \( UnPrimed \)) that takes a state predicate \( X \) (respectively, \( X' \)) and substitutes each variable in \( X \) (respectively, \( X' \)) with its primed (respectively, unprimed) version, thereby returning a state predicate \( X' \) (respectively, \( X \)). The function \( getPrimed \) (respectively, \( getUnPrimed \)) takes a transition predicate \( T \) and returns a primed (respectively, an unprimed) state predicate representing the set of destination (respectively, source) states of all transitions in \( T \).

**BG example.** We define a state predicate \( I_1 \) that captures the set of states in which the general is not Byzantine and at most one non-general could be Byzantine. (Process variables \( p \) and \( q \) represent non-general processes in the quantifications.)

\[
I_1 = \neg b.g \land (\neg b.j \lor \neg b.k) \land (\neg b.k \lor \neg b.l) \land (\neg b.l \lor \neg b.j) \land \\
(\forall p :: \neg b.p \Rightarrow (d.p = \bot \lor d.p = d.g)) \land \\
(\forall p :: (\neg b.p \land f.p) \Rightarrow (d.p \neq \bot))
\]

In this case, a non-general non-Byzantine process is either undecided or its decision is the same as that of general. Moreover, all non-general non-Byzantine processes that are finalized have

---

3An individual state \( s \), the empty set, and the entire state space (i.e., the universal set) are special cases of a state predicates.
decided on a non-⊥ value. As another example, the state predicate $I_2$ captures a set of states where the general is Byzantine and all non-generals have decided on the same value.

$$I_2 = b.g \land \neg b.j \land \neg b.k \land \neg b.l \land (d.j = d.k = d.l \land d.j \neq ⊥)$$

Closure. A state predicate $X$ is closed in an action $grd \rightarrow stmt$ iff executing $stmt$ from a state $s \in (X \land grd)$ results in a state in $X$. We say a state predicate $X$ is closed in a program $p$ iff $X$ is closed all actions of $p$.

BG example. The state predicates $I_1$ and $I_2$ are closed in actions $BG_1$ and $BG_2$. We leave it to the reader to verify this claim.

Program computations and execution semantics. We consider a nondeterministic interleaving of all program actions generating a sequence of states. A computation of a program $p = \langle V_p, \Pi_p \rangle$ is a sequence $\sigma = \langle s_0, s_1, \cdots \rangle$ of states that satisfies the following conditions: (1) for each transition $(s_i, s_{i+1})$ ($i \geq 0$) in $\sigma$, there exists an action $grd \rightarrow stmt$ in some process $P_j \in \Pi_p$ such that $grd$ holds at $s_i$ and the execution of $stmt$ at $s_i$ yields $s_{i+1}$; (2) $\sigma$ is maximal in that either $\sigma$ is infinite or if it is finite, then no action is enabled in its final state, and (3) $\sigma$ is fair; i.e., if a process $P_j$ is continuously enabled in $\sigma$, then eventually some action of $P_j$ will be executed.

Distribution model. We model distribution issues as a set of read/write restrictions imposed on program processes. More specifically, we associate with each process $P_j$ a set of variables that it is allowed to read, denoted $r_j$, and a set of variables that $P_j$ can write, denoted $w_j$. We assume that for each process $P_j$, $w_j \subseteq r_j$; i.e., if a process can write a variable, then that variable is readable too. No action in a process $P_j$ is allowed to update a variable $v \not\in w_j$. This constraint can be specified as the transition predicate $rwRest \equiv (\forall v : v \notin w_j : v = v')$; i.e., the value of an unprimed variable $v \not\in w_j$ should be equal to the value of its primed version. Note that the transition predicate $rwRest$ imposes a similar constraint on unreadable variables because if a variable cannot be read, then it cannot be written either. Using read/write restrictions $rwRest$, we formally specify an action $grd \rightarrow stmt$ as a transition predicate $grd \land Primed(stmtExpr) \land rwRest$, where $stmtExpr$ is a Boolean expression generated from the assignment $stmt$. For example, an
assignment $x := 1$ can be specified as the expression $x' = 1$.

**BG example.** Each non-general non-Byzantine process $P_j$ is allowed to only read $r_j = \{b.j, d.j, f.j, d.k, d.l, d.g\}$ and it can only write $w_j = \{d.j, f.j\}$. Hence, we have $w_j \subseteq r_j$. As an example of a transition predicate, we represent the action $BG_1$ as $((d.j = \bot) \land (f.j = 0)) \land (d.j' = d.g') \land rwRest$, where $rwRest$ is the transition predicate $(d.k = d.k') \land (d.l = d.l') \land (d.g = d.g') \land (b.g = b.g') \land (b.j = b.j') \land (b.k = b.k') \land (b.l = b.l') \land (f.k = f.k') \land (f.l = f.l')$.

**Specifications.** We follow Alpern and Schneider [18] in representing the specification $\text{spec}$ of a program as the conjunction of a safety specification (denoted $S$) and a liveness specification (denoted $L$); i.e., $\text{spec} = S \cap L$. Intuitively, $S$ stipulates that nothing bad ever happens. Formally, we represent $S$ as a transition predicate whose transitions must not appear in program computations. An action $grd \to stmt$ satisfies $S$ from a state predicate $X$ iff the transition predicate $X' \land grd \land \text{Primed}(stmtExpr) \land S \land rwRest$ is equal to the empty set, where $rwRest$ captures the read/write restrictions of the process that executes the action. A program $p$ satisfies its safety specification $S$ from $X$ iff all actions of $p$ satisfy $S$ from $X$. In terms of program computations, a program satisfies $S$ from $X$ iff all program computations starting in $X$ satisfy $S$. A program computation $c = \langle s_0, s_1, \cdots \rangle$ satisfies $S$ from $X$ iff $(s_0 \in I) \land (\forall (s_i, s_{i+1}) : i \geq 0 : (s_i, s_{i+1}) \notin S)$. Otherwise, the computation $c$ violates $S$. The liveness specification $L$ states that something good will eventually occur. More precisely, we define $L$ as a set of infinite sequences of states. A computation is in $L$ if it contains a suffix$^4$ that is in $L$. Note that there may exist infinitely long sequences that have no suffix in the particular set of infinite sequences specified by $L$. For example, given a state $s$ that does not appear in any sequence $\langle s_0, s_1, \cdots \rangle$ belonging to $L$, the infinite sequence generated by a self-loop on $s$ would not belong to $L$. A computation $c = \langle s_0, s_1, \cdots \rangle$ satisfies $L$ from a state predicate $X$ iff $(s_0 \in I)$ and $c$ has a suffix in $L$. We say a program $p$ satisfies its liveness specification $L$ from a state predicate $X$ iff all computations of $p$ satisfy $L$ from $X$. A program $p$ satisfies its specification $\text{spec}$ from a state predicate $X$ iff $p$ satisfies its safety and liveness specifications from $X$.

**BG example.** The safety specification of the BG program requires that Validity and Agreement

---

$^4$A suffix of a sequence $\langle s_0, s_1, \cdots \rangle$ is a subsequence $\langle s_j, s_{j+1}, \cdots \rangle$ for some $j \geq 0$. **
be satisfied. Validity stipulates that if the general is not Byzantine and a non-Byzantine non-
general has finalized its decision, then the decision of that non-general process is the same as that
of the general. Agreement requires that if two non-Byzantine non-generals have finalized their
decisions, then their decisions are identical. Hence, the program should not execute transitions
that reach the primed state predicate $R_1$, where

$$R_1 = (\exists p, q :: \neg b.p' \land \neg d.p' \neq \bot \land \neg d.q' \neq \bot \land d.p' \neq d.q' \land f.p' \land f.q') \lor$$

$$\exists p :: \neg b.g' \land \neg d.p' \neq \bot \land d.p' \neq d.g' \land f.p'$$

Moreover, when a non-Byzantine process finalizes, it is not allowed to change its decision. Thus,
the set of transitions of the following transition predicate should not be executed as well:

$$S_2 = \neg b.j \land \neg f.j \land (d.j \neq d.j' \lor f.j = f.j')$$

Let $S_1$ be the transition predicate representing all transitions that reach a state in $R_1$. We specify
the safety specification of the BG program as the transition predicate $S_1 \lor S_2$.

**Invariants.** A state predicate $I$ is an invariant of a program $p$ for its specification $spec$ iff
the following conditions are satisfied: (1) $I$ is closed in $p$, and (2) $p$ satisfies $spec$ from $I$.

**BG example.** The state predicate $I_{BG} = I_1 \lor I_2$ is indeed an invariant of the BG program.

**Faults and fault-span.** We represent a fault-type $F$ as a set of actions. Fault actions
differ from program actions in that the program does not have execution control over fault
actions. A *computation of a program* $p = (V_p, \Pi_p)$ *in the presence of fault* $F$ is a sequence
$\sigma = \langle s_0, s_1, \cdots \rangle$ of states that satisfies the following conditions: (1) for each transition
$(s_i, s_{i+1})$ ($i \geq 0$) in $\sigma$, there exists either a program or a fault action $grd \rightarrow stmt$ such
that $grd$ holds at $s_i$ and the execution of $stmt$ at $s_i$ yields $s_{i+1}$; (2) $\sigma$ is *maximal*, and (3) $\sigma$ is
*fair*. A state predicate $FS$ is called a fault-span of a program $p$ from its invariant $I$ for fault
$F$ (denoted $F$-span) iff the following conditions are satisfied: (1) $I \Rightarrow FS$, and (2) $FS$ is
closed in program $p$ and fault actions. Intuitively, the $F$-span of $p$ from $I$ is a boundary
around $I$ to which the state of $p$ can be perturbed by fault and program actions.

**BG example.** The fault action $F_1$ may cause at most one non-Byzantine process to become
Byzantine. A Byzantine process may arbitrarily change its $d$ and/or $f$ values. (We include similar
fault actions for $k, l$ and $g$.)
\[ F_1 : \neg b.g \land \neg b.j \land \neg b.k \land \neg b.l \rightarrow b.j := true \]
\[ F_2 : b.j \rightarrow d.j, f.j := 0|1, false|true \]

In Section 5, we shall illustrate how to calculate the fault-span in a DiConic manner.

**Failsafe fault-tolerance.** A program \( p \) is failsafe \( F \)-tolerant from an invariant \( I \) for its specification \( spec \) (i.e., fault-tolerant against a fault-type \( F \)) iff there exists an \( F \)-span \( FS \) such that: (1) in the absence of fault \( F \), \( p \) satisfies \( spec \) from \( I \), and (2) in the presence of fault \( F \), the actions of \( p \) and \( F \) satisfy the safety of \( spec \) (i.e., \( S \)) from \( FS \).

## 3 Problem Statement

In this section, we reiterate the problem of adding failsafe fault-tolerance to programs from [10]. Specifically, to formulate our DiConic approach in terms of the satisfiability problem, we represent the addition problem in terms of state/transition predicates.

In order to separate fault-tolerance from functional concerns, the problem of adding fault-tolerance stipulates that no new behaviors are added to programs in the absence of faults. More precisely, given a program \( p = \langle V_p, \Pi_p \rangle \), its invariant \( I \), its specification \( spec = S \cap L \) and a fault-type \( F \), we aim to generate a revised version of \( p \), denoted \( p^f = \langle V_p, \Pi_p^f \rangle \) with a new invariant \( I^f \) such that \( p^f \) is failsafe \( F \)-tolerant from \( I^f \) for \( spec \). If \( I^f \) includes a state \( s \) that does not belong to \( I \), then the execution of \( p \) in the absence of \( F \) from \( s \) may generate new computations. Hence, we require that \( I^f \Rightarrow I \). Moreover, starting in \( I^f \), the actions of \( p^f \) should not include new transitions. Otherwise, \( p^f \) may exhibit new behaviors in the absence of faults. Thus, for each action \( grd^f \rightarrow stmt^f \) in \( p^f \), we require that there exists an action \( grd \rightarrow stmt \) in \( p \) such that the transition predicate \( I^f \land grd^f \land Primed(stmt^f Expr) \land rwRest \) implies the transition predicate \( I^f \land grd \land Primed(stmtExpr) \land rwRest \). Therefore, we formally state the problem of adding failsafe fault-tolerance as follows:

\[^5d.j := 0|1 \text{ means that } d.j \text{ could be assigned either } 0 \text{ or } 1.\]
The Problem of Adding Failsafe Fault-Tolerance.

Given $p$, $\mathcal{I}$, $\text{spec}$, and $F$, identify $p^f$ and $\mathcal{I}^f$ such that

1. $\mathcal{I}^f \Rightarrow \mathcal{I}$,

2. For each action $grd^f \rightarrow stmt^f$ in $p^f$, there exists some action $grd \rightarrow stmt$ in $p$ such that
   \[
   (\mathcal{I}^f \land grd^f \land \text{Primed}(stmt^f\text{Expr}) \land rwRest) \Rightarrow 
   (\mathcal{I}^f \land grd \land \text{Primed}(stmt\text{Expr}) \land rwRest)
   \]
   where $rwRest$ captures the read/write restrictions of the process that executes the action $grd^f \rightarrow stmt^f$.

3. $p^f$ is failsafe $F$-tolerant from $\mathcal{I}^f$ for $\text{spec}$. □

4 Adding Failsafe Fault-Tolerance

In order to simplify the presentation of our DiConic approach, in this section, we present an intuitive description of the algorithm presented in previous work [12, 17] for the addition of fault-tolerance to integrated models of distributed programs. This algorithm (see Figure 1) takes a non-deterministic finite-state machine representing the fault-intolerant program and generates a state machine representing the failsafe fault-tolerant program.

The algorithm in Figure 1 first identifies a valid fault-span of the program that is a superset of the invariant and is closed in program and fault transitions. Subsequently, the algorithm computes and removes the set of offending states from where a sequence of fault transitions can directly violate safety. The removal of offending states is accomplished by making them unreachable. Then the algorithm identifies and removes a set of offending transitions that either directly violate safety or reach an offending state. However, since the offending states are made unreachable in Step 2, offending transitions that start in an offending state need not be removed. While removing offending states/transitions, the addition algorithm may introduce states that have no outgoing transitions; i.e., deadlock states. The exclusion of deadlock states from the invariant may leave transitions that start in the new invariant and reach a recently removed state, thereby violating the closure of the new invariant. These transitions are removed in Step 5. The algorithm iterates through Steps 4 and 5 until either all invariant states are removed or a closed non-empty invariant is found. Existing implementations [12, 13, 17] of the algorithm in Figure 1 execute all steps on an integrated model.
Step 2: Remove the set of offending states in the F-span from where a sequence of fault transitions alone violates safety; i.e., make the offending states unreachable.

Step 3: Remove a set of offending transitions that either directly violate safety or reach the set of offending states. (Heuristic: Transitions that violate safety and start in an offending state need not be removed since offending states are made unreachable in the previous step)

Step 4: Remove deadlocks in the invariant

Is the new invariant empty?
- Yes: Declare failure
- No: Is the new invariant closed?
  - Yes: Declare success
  - No:

Step 5: Ensure the closure of the new invariant

represented either as a non-deterministic finite-state machine [12] or as a set of symbolic entities (e.g., BDDs) [13], thereby making it difficult to scale these algorithms as the number of program processes increases.

5 DiConic Addition

In this section, we present our DiConic algorithm. Specifically, in Section 5.1, we illustrate how to compute the fault-span and the set of offending states (Steps 1 and 2 in Figure 1). In Section 5.2, we present a DiConic method for removing offending transitions (Step 3 in Figure 1). Finally, in Section 5.3, we calculate a new invariant for the synthesized failsafe program in a DiConic fashion. This step corresponds to the loop that includes Steps 4 and 5 in Figure 1.
5.1 Computing Fault-Span and Offending States

In this section, we decompose the problem of calculating a fault-span and the set of offending states by introducing a distributed forward/backward reachability algorithm. Specifically, in calculating the fault-span using forward reachability, the integrated algorithms [12, 13, 17] implement a fixpoint computation that explicitly explores the set of states reachable from the invariant of the fault-intolerant program by all program and fault transitions. In each iteration, the forward reachability algorithm computes a new set of states reachable from previously calculated states. Continuing thus, the forward reachability algorithm reaches a point where no more states are reachable. The union of the sets of all states computed in all iterations comprises the fault-span of the fault-intolerant program. Instead of calculating a set of states reachable from a given state predicate $X$, in each iteration, the backward reachability algorithm computes a set of states from where $X$ is reached.

Our proposed DiConic approach for the calculation of the fault-span (respectively, the set of offending states) is a divide-and-conquer fixpoint computation with two kinds of components, namely the coordinator and the reachability nodes. A reachability node contains a single program action and computes the set of states reached by the execution of that action from a state predicate $X$ (respectively, the set of states from where the execution of that action reaches a state in $X$). The coordinator node manages the reachability nodes. Figures 2 and 3 illustrate the two components of our DiConic approach for forward reachability. (We omit the DiConic backward reachability algorithm as it is similar to the forward reachability.) The coordinator starts by sending out a $Base$ state predicate to all nodes. Each node computes the set of states outside $Base$ that are reachable from $Base$ by that node’s action (see Figure 2). The coordinator takes the union of all reachable states, denoted $reachedStates$, calculated by all nodes. If this union is empty, then the fixpoint computation is terminated. Otherwise, another iteration starts with a new $Base$, which is the union of the old $Base$ and the state predicate $reachedStates$. For the calculation of the fault-span, the $Base$ predicate is the invariant of the fault-intolerant program, and corresponding to each program and fault action, a reachability node is instantiated. Note that for the calculation of the set of offending states using DiConic backward reachability, only fault actions are considered since
we want to compute the set of states from where safety is violated by a sequence of fault transitions \textit{alone}. Specifically, for each fault action, we first identify the set of states from where that action directly violates safety. The union of all such states comprises the base set for a backward reachability computation using only fault actions. Therefore, in the rest of this section, we present our DiConic approach assuming that the fault-span, denoted \( FS \), and the set of offending states, denoted \( OS \), have already been calculated.

**BG example.** In order to calculate the fault-span of the canonical BG program, denoted \( FS_{BG} \), we instantiate 14 forward reachability nodes as we have 2 program actions and 2 fault actions corresponding to each non-general process and 2 fault actions corresponding to the general process. We also create a reachability coordinator. The base predicate is equal to the invariant \( I_{BG} \). We consider only the program/fault actions of process \( P_j \) as they are structurally similar to other non-general processes. Clearly, in the first iteration of the fixpoint computation, starting from the invariant, program actions \( BG_1 \) and \( BG_2 \) would reach to a state in the invariant (due to the closure of the invariant in program actions).

The reachability node corresponding to the fault action \( F_1 \) returns \( I_1 \lor (b.g \land \neg b.j \land \neg b.k \land \neg b.l) \) as the set of states reachable from the invariant by \( F_1 \). Specifically, starting from the state predicate \( I_1 \) (see Section 2) in the invariant, if the fault action \( F_1 \) does not cause the general
process $P_g$ to become Byzantine, then the set of states reached from $I_1$ is the same as $I_1$. Nonetheless, if $P_g$ becomes Byzantine, then the $b$ values of non-general processes would remain false as at most one process could be Byzantine. Thus, the set of states reached from $I_1$ by faults is $(I_1 \lor (b.g \land \neg b.j \land \neg b.k \land \neg b.l))$. If the BG program is in a state in $I_2$, then the fault action $F_1$ will not be executed as $P_g$ is already Byzantine.

The reachability node corresponding to the fault action $F_2$ returns the same predicate as that of $F_1$. If $P_j$ is Byzantine, then the execution of the action $F_2$ from $I_1$ would not violate the closure of $I_1$ since the second and the third conjuncts of $I_1$ are specified for non-Byzantine processes. Moreover, $F_2$ will not be enabled from $I_2$. If $P_g$ is Byzantine, then $F_2$ will not be enabled from $I_1$, thereby preserving the closure of $I_1$. In this case, a similar reasoning as that for $F_1$ would yield $I_2$ as the set of states reachable from $I_2$ by $F_2$.

Since the state predicate $I_1 \lor (b.g \land \neg b.j \land \neg b.k \land \neg b.l)$ is closed in all program and fault actions, the fault-span of the BG program is equal to $FS_{BG}$, where

$$FS_{BG} = I_1 \lor (b.g \land \neg b.j \land \neg b.k \land \neg b.l).$$

ReachabilityCoordinator(Base: state predicate)
{  // $N$ denotes the total number of program and fault actions.
    - $X := Base$;
    - repeat {
        - Send $X$ to all nodes;
        - Wait for reachedStates$_i$ from Node$_i$;
        - reachedStates := reachedStates$_1 \lor \cdots \lor$ reachedStates$_N$;
        - $X := X \lor$ reachedStates;
    } until(reachedStates = $\emptyset$);
    - Send termination signal to all nodes;
    - return $X$;
}

Figure 3: Reachability coordinator in DiConic forward reachability.

Both fault actions may violate safety if they start in a state in $UnPrimed(R_1)$ (see Section 2); i.e., the base set for backward reachability is $R_1$. Subsequently, we compute the set of all states from where the execution of fault actions would yield a state in $R_1$. The fault actions $F_1$ and $F_2$ yield a state in $R_1$ only if they are enabled in $UnPrimed(R_1)$. Therefore, the second iteration of the fixpoint computation is the last iteration, returning $UnPrimed(R_1)$ as the set of offending
5.2 Removing Offending Transitions

We decompose the removal of the offending transitions into the elimination of such transitions in each action without actually creating an integrated model of the program. Specifically, each synthesis node investigates two cases for the existence of offending transitions in the set of transitions represented by its associated action. Steps 1 and 2 in Figure 4 identify and exclude a subclass of the offending transitions that start outside the set of offending states and reach an offending state. The motivation behind these steps is that such transitions take the program to states from where the occurrence of faults may violate safety. Thus, in order to preserve safety even when faults occur, the program must not take such transitions. Steps 3 and 4 in Figure 4 determine and remove another subclass of the offending transitions that start outside the invariant in the fault-span $\mathcal{FS}$ and directly violate the safety specification.

In the next subsection, we describe how to divide the task of resolving deadlock states that may be created due to the elimination of offending transitions.

BG example. We create two synthesis nodes corresponding to the actions $BG_1$ and $BG_2$. The execution of Steps 1 and 2 in Figure 4 for the action $BG_1$ returns an empty set since the only way the execution of $BG_1$ generates a state in the set of offending states is that $BG_1$ is enabled in an offending state. In other words, the action $BG_1$ may violate safety if it is enabled in a state in the fault-span where the general is Byzantine and the other two non-generals have finalized with different decisions. However, since such states have already been included in the set of offending states and Steps 1 and 2 of the Synthesis Node ensure that the offending states are not reached, we do not have to exclude such transition from the action $BG_1$. Therefore, the first two steps of the Synthesis Node algorithm do not change action $BG_1$.

The synthesis node corresponding to $BG_2$ revises $BG_2$ in the following way. Specifically, if the action $BG_2$ is enabled from a state outside the set of offending states where a non-general non-Byzantine process has finalized with a different decision from that of $P_j$, then the safety of specification will be violated if $P_j$ finalizes its decision. Thus, a set of transitions starting in $(d.k \neq \bot \land d.j \neq d.k) \lor (d.l \neq \bot \land d.j \neq d.l)$ would be excluded from $BG_2$ in Steps 1 and
2 of Synthesis_Node. Steps 3 and 4 do not exclude any additional transitions from $BG_2$ as the only transitions that directly violate safety upon finalization are the same transitions excluded in Steps 1 and 2. Therefore, the revised action $BG_2$ is as follows:

$$BG_2: \quad (d.j \neq \bot \land f.j = 0) \land (d.k = \bot \lor d.j = d.k) \land (d.l = \bot \lor d.j = d.l) \quad \rightarrow \quad f.j := true$$

In the case of the BG program, the synthesis nodes associated with the actions of $P_k$ and $P_l$ perform revisions similar to that of synthesis nodes associated with $BG_1$ and $BG_2$. 

Figure 4: Synthesis node.
5.3 Computing a New Invariant

In this section, we illustrate how our DiConic approach decomposes the problem of calculating a new invariant for the failsafe program by the collaboration of the \texttt{Synthesis\_Node} and the \texttt{Synthesis\_Coordinator} algorithms (see Figures 4 and 5). First, the \texttt{Synthesis\_Coordinator} algorithm ensures that the removal of offending states does not lead to the removal of all invariant states (see Steps 1 and 2 in Figure 5). Then the \texttt{Synthesis\_Coordinator} enters a loop which synchronizes the activities of all synthesis nodes once they start participating in the calculation of the new invariant (see the loop in Steps 5-9 in Figure 4). These two loops are in fact a DiConic implementation of the loop that includes Steps 4 and 5 in Figure 1. The \texttt{Synthesis\_Coordinator} waits to receive the revised guards from all synthesis nodes after the removal of offending transitions in Steps 1-4 of the \texttt{Synthesis\_Node} algorithm. The synthesis nodes enter a waiting state after sending their revised guard to the coordinator. The \texttt{Synthesis\_Coordinator} calculates the set of all invariant states from where no action is enabled (see Steps 4 and 5 in Figure 5); i.e., deadlock states. Afterwards, the coordinator computes a new invariant by removing the deadlock states. The \texttt{Synthesis\_Coordinator} sends the new invariant and a state predicate representing deadlock states to all synthesis nodes. If the new invariant becomes empty, then \texttt{Synthesis\_Coordinator} declares failure in the addition of failsafe fault-tolerance. After receiving the new invariant, each synthesis node determines whether or not its associated action includes transitions that reach a state outside the invariant $\text{Inv}_{\text{new}}$ (Steps 8 and 9 in Figure 4); i.e., violates the closure of the invariant. An action violates the closure of the invariant if it contains transitions that reach states that have been excluded by other actions in other synthesis nodes. Afterwards, each synthesis node starts another iteration by sending its revised guard $\text{grd}$ to the coordinator. The collaboration between the synthesis coordinator and synthesis nodes continues until either a valid new invariant is found or the synthesis fails.

BG example. Since the invariant $\mathcal{I}_{BG}$ does not include any offending states (i.e., $\mathcal{I}_{BG} \cap \text{UnPrimed}(\mathcal{R}_1) = \emptyset$), the revision of the action $BG_2$ does not create new deadlock states in the invariant. Thus, the predicate $\text{DeadlockStates}$ computed in Step 5 of Figure 5 is equal to the empty set. As a result, the synthesis nodes exit the repeat-until loop in the first iteration.
 Therefore, the invariant of the failsafe program is equal to $\mathcal{I}_{BG}$.

**Theorem 5.1** DiConic addition of failsafe fault-tolerance is sound.

**Proof.** Let $p = \langle V_p, \Pi_p \rangle$ be the input fault-intolerant program with its invariant $\mathcal{I}$, its specification $spec$, and a fault-type $F$. Also, let $p^f = \langle V_p, \Pi^f_p \rangle$ be the program synthesized by our DiConic method (i.e., algorithms `Synthesis_Coordinator` and `Synthesis_Node`) and $\mathcal{I}^f$ be the invariant of $p^f$. Since the `Synthesis_Coordinator` algorithm only removes states from $\mathcal{I}$, $\mathcal{I}^f$ is a subset of $\mathcal{I}$. Also, by construction, we have $\mathcal{I}^f \land OS \equiv \text{false}$. Likewise, the `Synthesis_Node` algorithm only removes offending and closure-violating transitions from an action. Thus, by construction, no action in $p^f$ includes new transitions, and all actions of $p^f$ satisfy the safety of $spec$. Therefore, $p^f$ meets the first and second requirements of the addition problem (see Section 3).

Moreover, if the synthesis is successful, then $\mathcal{I}^f$ is non-empty and does not have any deadlock states. Since no new transitions are included in the actions of $p^f$, starting from $\mathcal{I}^f$, the set of computations of $p^f$ in the absence of faults is a subset of the set of computations of $p$ starting in $\mathcal{I}^f$. Thus, in the absence of faults, $p^f$ satisfies $spec$ from $\mathcal{I}^f$.

Now, let $c = \langle s_0, s_1, \cdots \rangle$ be a computation of $p^f$ in the presence of $F$ in which a transition

```plaintext
Synthesis_Coordinator(Inv, OS: state predicate)
{ /* OS denotes the set of offending states. */
  /* n denotes the number of program actions. */
  - Inv_new := Inv \land \neg OS;
  - If (Inv_new is unsatisfiable) then
    - declare that a failsafe program cannot be synthesized; exit();
  repeat
    - Wait for the revised guards $grd_1, \cdots, grd_n$ from synthesis nodes $Node_1, \cdots, Node_n$;
    - Guards := $grd_1 \lor \cdots \lor grd_n$;
    - DeadlockStates := (Inv_new \land \neg Guards);
    - Inv_new := Inv_new \land \neg DeadlockStates;
    - Send Inv_new and DeadlockStates to nodes $Node_1, \cdots, Node_n$;
  until ((Inv_new is unsatisfiable) \lor (DeadlockStates is unsatisfiable));
  - If (Inv_new is unsatisfiable) then
    - declare failure in synthesizing a failsafe program; exit();
  - Notify nodes of successful termination;
}
```

Figure 5: Synthesis coordinator.
$(s_i, s_{i+1})$, for $i \geq 0$, violates the safety of $spec$. If $(s_i, s_{i+1})$ is a program transition, then there must be an action in $p^f$ that includes $(s_i, s_{i+1})$ and violates safety. This is a contradiction with the fact that all offending transitions have been removed from $p^f$. If $(s_i, s_{i+1})$ is a fault transition, then $s_i$ is a reachable offending state. The transition $(s_{i-1}, s_i)$ cannot be a program transition because it would be an offending transition. Thus, $(s_{i-1}, s_i)$ is a fault transition and $s_{i-1}$ is an offending state. By induction, it follows that $s_0$ is an offending state. However, since all computations start in the invariant, we have $s_0 \in \mathcal{I}^f$, which is a contradiction as all offending states have been removed from $\mathcal{I}^f$. Therefore, $p^f$ is failsafe $F$-tolerant from $\mathcal{I}^f$ for $spec$.

Comment on the completeness of our approach. The elimination of closure-violating transitions in each synthesis node may create new deadlock states in the invariant. The number of such deadlock states depends on how appropriate closure-violating transitions are selected for elimination among all program actions. The current strategy for eliminating closure-violating transitions may result in the removal of an inappropriate set of such transitions, thereby leading to the failure of the addition of fault-tolerance to the program at hand; i.e., our algorithm may fail to find a failsafe program while there exists one.

6 Case Studies

In this section, we present three additional case studies of the application of our DiConic approach in adding failsafe fault-tolerance. Specifically, in Subsection 6.1, we add failsafe fault-tolerance to a simplified version of an altitude switch (ASW) controller. We have chosen this example to compare the failsafe fault-tolerant program synthesized in a divide-and-conquer approach with the ASW program that has been manually designed in [16]. In Subsection 6.2, we illustrate how to add failsafe fault-tolerance in a DiConic way to the controlling program of a Cruise Control System (CCS) (adapted from [24]). Finally, in Subsection 6.3, we demonstrate how DiConic addition of fault-tolerance simplifies the synthesis of a token ring program that tolerates state-corruption faults without violating its safety specification. We note that we have formulated these case studies in terms of the satisfiability problem and have employed the Yices SMT solver to validate our approach.
The Yices specifications of these case studies are available in the Appendix.

6.1 Altitude Switch Controller

In this section, we demonstrate the application of our DiConic approach in adding fail-safe fault-tolerance to a simplified version of an altitude switch (ASW) controller program (adapted from [16]).

The fault-intolerant altitude switch (ASW). The ASW program monitors a set of input variables and generates an output. Also, the program has a set of internal variables as follows: (i) AltBelow is equal to 1 if the altitude is below a specific threshold, otherwise, it is equal to 0; (ii) ActuatorStatus is equal to 1 if the actuator is powered on, otherwise, it is equal to 0; (iii) Inhibit is equal to 1 when the actuator power-on is inhibited, otherwise, it is equal to 0, and (iv) Reset is equal to 1 if the system is being reset.

The ASW program has a mode variable Mode and can be in three different modes: (i) the Initialization mode when the ASW system is initializing, denoted Mode = I; (ii) the Await-Actuator mode if the system is waiting for the actuator to power on, denoted Mode = AA, and (iii) the Standby mode, denoted Mode = SB.

Moreover, we model the signals that come from the input sensors to indicate the occurrence of faults using the following variables: (i) if the system fails in the initialization mode, then the variable InitFail will be set to 1, otherwise, InitFailed remains 0; (ii) if the altitude sensors fail and do not recover in a certain number of built-in reset attempts, then the variable AltFail will be equal to 1, otherwise, AltFail remains 0, and (iii) if the Actuator fails in the Await-Actuator mode, then the variable ActFail will be equal to 1, otherwise, ActFail remains 0. The domain of all variables except Mode is equal to \{0, 1\}. The fault-intolerant program consists of only one process with the following actions:
The program changes its mode from Initialization to Standby. The program goes to the Initialization mode when it is either in Standby or in Await-Actuator mode and the reset signal is received. If the program is in the Standby mode, the altitude is below a predetermined threshold, the actuator power-on is not inhibited and the actuator is not powered on, then the program changes its mode to Await-Actuator. In the Await-Actuator mode, the program either powers on the actuator and goes to the standby mode, or enters the initialization mode upon receiving the reset signal.

**Read/Write restrictions.** All variables can be read. However, the program cannot write the variables `InitFail`, `AltFail`, `ActFail`, `AltBelow` and `Inhibit`.

**Faults.** If the altitude sensors incur malfunction then the state of the program will be perturbed to a faulty state. We represent the fault actions as follows:

\[
\begin{align*}
F_1 & : \ (InitFail = 0) \quad \rightarrow \quad InitFail := 1; \\
F_2 & : \ (AltFail = 0) \quad \rightarrow \quad AltFail = 1; \\
F_3 & : \ (ActFail = 0) \quad \rightarrow \quad ActFail = 1;
\end{align*}
\]

The guards of the above actions represent conditions under which the program detects the occurrence of faults.

**Safety specification.** The problem specification requires that the program does not change its mode from Standby to Await-Actuator if the altitude sensors are failed; i.e., `AltFail` is equal to 1. Moreover, if the initialization has failed, then the ASW program must not enter the Standby mode. Finally, if the actuator fails in the AA mode, then the ASW program should not power on the actuator. Thus, we represent the safety specification of the ASW program by the transition predicate $S_{ASW}$, where
\[ S_{ASW} = ((\text{AltFail} = 1) \land (\text{Mode} = \text{SB}) \land (\text{Mode}' = \text{AA})) \lor \\
(\text{InitFail} = 1) \land (\text{Mode} = \text{I}) \land (\text{Mode}' = \text{SB}) \lor \\
(\text{ActFail} = 1) \land (\text{Mode} = \text{AA}) \land (\text{ActuatorStatus} = 0) \land (\text{ActuatorStatus}' = 1) \]

This transition predicate specifies the set of transitions that must not appear in any computation of the ASW program even when faults occur.

**Invariant.** If the *Inhibit* is activated, then the actuators should not be powered on. Moreover, the program should not be in a faulty mode. Thus, the invariant of the ASW program is equal to \( I_{ASW} \), where

\[ I_{ASW} = ((\text{Inhibit} = 1) \Rightarrow (\text{ActuatorStatus} = 0)) \land \\
(\text{InitFail} = 0) \land (\text{AltFail} = 0) \land (\text{ActFail} = 0) \]

**DiConic calculation of the fault-span and offending states.** In DiConic forward reachability on fault actions, in the first iteration, the fault action \( F_1 \) reaches the state predicate \( \text{reachedStates}_1 \equiv ((\text{Inhibit} = 1) \Rightarrow (\text{ActuatorStatus} = 0)) \land (\text{InitFail} = 1) \) from the invariant \( I_{ASW} \). Likewise, the reachability nodes corresponding to \( F_2 \) and \( F_3 \) respectively send the following set of reached states to the reachability coordinator: \( \text{reachedStates}_2 \equiv ((\text{Inhibit} = 1) \Rightarrow (\text{ActuatorStatus} = 0)) \land (\text{AltFail} = 1) \) and \( \text{reachedStates}_3 \equiv ((\text{Inhibit} = 1) \Rightarrow (\text{ActuatorStatus} = 0)) \land (\text{ActFail} = 1) \). Thus, since program actions are closed in the invariant, the set of states reachable by fault and program actions in the first iteration of the repeat-until loop in Figure 3 is equal to \( \mathcal{FS}_{ASW} = ((\text{Inhibit} = 1) \Rightarrow (\text{ActuatorStatus} = 0)) \land ((\text{InitFail} = 1) \lor (\text{AltFail} = 1) \lor (\text{ActFail} = 1)) \). The set of states reachable from \( \mathcal{FS}_{ASW} \) by fault and program actions would yield no new states outside \( \mathcal{FS}_{ASW} \), thereby returning \( \mathcal{FS}_{ASW} \) as the fault-span of the ASW program for fault actions \( F_1, F_2 \) and \( F_3 \). Since fault actions do not directly violate safety specification, the base set of states for backward reachability is empty. Therefore, the set of offending states is empty.

**Removing the set of offending transitions.** We create five synthesis nodes corresponding to the actions \( A_1-A_5 \). In addition to an action \( A_i \) \( (1 \leq i \leq 5) \), each synthesis node \( \text{Node}_i \) takes the invariant \( I_{ASW} \), the fault-span \( \mathcal{FS}_{ASW} \), the safety specification \( S_{ASW} \), the set of offending states \( OS \) and the write restrictions as its inputs. Since \( OS = \emptyset \), the first two steps
in Figure 4 result in an unsatisfiable transition predicate. Next, we describe the results of executing Steps 3 and 4 in each Node.

- **Action** $A_1$. Step 3 calculates the transition predicate $(\text{Mode} = I) \land (\text{InitFail} = 1) \land (\text{Mode}' = SB)$ as the set of transitions that violate the safety specification and should be excluded from action $A_1$. Therefore, action $A_1$ would be revised as follows:

  $\left( \text{Mode} = I \right) \land (\text{InitFail} = 0) \rightarrow \text{Mode} := SB$;

- **Action** $A_2$. Since the safety specification $S_{\text{ASW}}$ does not stipulate anything about changing the program mode to initialization, this action does not include any offending transitions. Therefore, $A_2$ remains unchanged.

- **Action** $A_3$. The safety specification $S_{\text{ASW}}$ states that the ASW program must not enter the AA mode if the altitude sensors have failed (i.e., $\text{AltFail} = 1$). Thus, the synthesis node corresponding to action $A_3$ revises $A_3$ as follows:

  $\left( \text{Mode} = SB \right) \land (\text{AltBelow} = 1) \land (\text{Inhibit} = 0) \land (\text{ActuatorStatus} = 0) \land (\text{AltFail} = 0) \rightarrow \text{Mode} := AA$;

- **Action** $A_4$. If faults cause the actuator to fail, then the program should not power on the actuator. Thus, due to the execution of the fault action $F_3$, action $A_4$ may be enabled in states where $\text{ActFail} = 1$ holds, thereby leading to the violation of safety. The elimination of such transitions originated in the fault-span outside the invariant results in the following revised action:

  $\left( \text{Mode} = AA \right) \land (\text{ActuatorStatus} = 0) \land (\text{Inhibit} = 0) \land (\text{ActFail} = 0) \land (\text{ActuatorStatus} = 1) \rightarrow \text{Mode} := SB$;

- **Action** $A_5$. This action remains unchanged for the same reason as that of action $A_2$.

Since the set of offending states is empty, no state is removed from the invariant. Therefore, the invariant of the failsafe program is equal to $\mathcal{I}_{\text{ASW}}$. We note that the failsafe ASW program synthesized in this section is similar to the ASW program that has been manually designed in [16].
6.2 Cruise Control System

In this section, we present a case study on the application of our DiConic approach in adding failsafe fault-tolerance to the controlling program of a Cruise Control System (CCS). The cruise control example in this section is a simplified version of the example in [24].

The fault-intolerant CCS program. The CCS program has 4 input variables Ignition, EngState, Brake, and Lever that represent the values of the input signals. (To distinguish variables from their values, system variables start with capitalized letters.) The domain of the variable Ignition contains values of on and off that represent the state of the ignition switch. The variable EngState represents the working state of the engine with the domain \{running, off\}. The variable Brake illustrates the state of an input signal from the brakes that shows whether or not the driver has applied the brakes. The domain of Brake is equal to \{notApplied, applied, unknown\}. The Lever variable represents the position of the cruise control lever set by the driver. The cruise control lever can be in three positions off, constant, and resume. The CCS program also has a variable SysMode that stores its operating mode. The CCS program can be in the following modes: off, inactive, cruise, and override. If the CCS program is in none of the above-mentioned modes then its mode is unknown. We represent the fault-intolerant CCS program by the actions  $A_1$-  $A_9$.

\[
\begin{align*}
A_1 & : \quad ((SysMode = off) \land (Ignition = on)) \quad \rightarrow \quad SysMode := inactive; \\
A_2 & : \quad ((SysMode = inactive) \land (Ignition = off)) \quad \rightarrow \quad SysMode := off; \\
A_3 & : \quad ((SysMode = inactive) \land (Lever = constant) \land (Ignition = on) \land \\
& \quad (EngState = running)) \\
& \quad \rightarrow \quad SysMode := cruise; \\
A_4 & : \quad ((SysMode = cruise) \land (Ignition = off)) \quad \rightarrow \quad SysMode := off; \\
A_5 & : \quad ((SysMode = cruise) \land (EngState = off)) \quad \rightarrow \quad SysMode := inactive; \\
A_6 & : \quad ((SysMode = cruise) \land ((Brake = applied) \lor (Lever = off))) \\
& \quad \rightarrow \quad SysMode := override; \\
A_7 & : \quad ((SysMode = override) \land (Ignition = off)) \quad \rightarrow \quad SysMode := off; \\
A_8 & : \quad ((SysMode = override) \land (EngState = off)) \quad \rightarrow \quad SysMode := inactive; \\
A_9 & : \quad ((SysMode = override) \land (Ignition = on) \land (EngState = running) \land \\
& \quad ((Lever = constant) \lor (Lever = resume))) \quad \rightarrow \quad SysMode := cruise;
\end{align*}
\]

If the program is in the off mode and the ignition is on then the program transitions to the inactive mode (Action  $A_1$). The program transitions to the off mode if it is in the inactive
mode and the ignition turns off (Action $A_2$). In the inactive mode, if (i) the lever is set on constant, (ii) the ignition is on, and (iii) the engine is running, then the program transitions to the Cruise mode (Action $A_3$). In the cruise mode, the program transitions to (i) the off mode if the ignition turns off (Action $A_4$), or (ii) the inactive mode when the engine turns off (Action $A_5$). If the lever is off or the driver has applied the brakes, then the program moves to the override mode from cruise mode (Actions $A_6$). In the override mode, the program goes to the off mode if the ignition turns off (Action $A_7$). If the engine turns off then the program will transition to the inactive mode from the override mode (Action $A_8$). Finally, in the override mode, the program transitions to the cruise mode if (i) the ignition is on, (ii) the engine is running, and (iii) the lever is on constant or resume (Action $A_9$).

The invariant of the CCS program. In general, the CCS program should be in one of the modes off, inactive, cruise, or override, and the brakes subsystem should also be working properly. Also, if the program is in the off mode then the ignition should be off. If the program is in the inactive mode then the ignition should be on. If the program is in the cruise mode, then the ignition should be on, the engine should be running, the lever should not be off, and the brakes must not be applied. In the override mode, the ignition is on and the engine should be running. Hence, we represent the invariant of the CCS program by the state predicate $\mathcal{I}_{\text{CCS}}$, where

\[
\mathcal{I}_{\text{CCS}} = ((\text{SysMode} \neq \text{unknown}) \land (\text{Brake} \neq \text{unknown})) \land \mathcal{I}_1, \text{ where}
\]

\[
\mathcal{I}_1 = ((\text{SysMode} = \text{off}) \lor (\text{SysMode} = \text{inactive}) \lor (\text{SysMode} = \text{cruise}) \lor (\text{SysMode} = \text{override})) \land
\]

\[
((\text{SysMode} = \text{off}) \Rightarrow (\text{Ignition} = \text{off})) \land
\]

\[
((\text{SysMode} = \text{inactive}) \Rightarrow (\text{Ignition} = \text{on})) \land
\]

\[
((\text{SysMode} = \text{cruise}) \Rightarrow ((\text{ignition} = \text{on}) \land (\text{EngState} = \text{running}) \land (\text{Brake} \neq \text{applied}) \land (\text{Lever} \neq \text{off}))) \land
\]

\[
((\text{SysMode} = \text{override}) \Rightarrow ((\text{Ignition} = \text{on}) \land (\text{EngState} = \text{running})))
\]

Read/Write restrictions. The CCS program can read all variables, however, it cannot write the variables Ignition, EngState, Brake, and Lever as they represent the values of the input signals.
Fault actions. The malfunction of the brake subsystem may corrupt the value of *Brake* to an unknown value. In addition, faults may perturb the cruise control system to an unknown operating mode. We represent the set of fault transitions by the following actions:

\[
F_1 : \ (Brake \neq \text{unknown}) \quad \rightarrow \quad Brake := \text{unknown}; \\
F_2 : \ (SysMode \neq \text{unknown}) \quad \rightarrow \quad SysMode := \text{unknown};
\]

The safety specification of the CCS program. The specification of the CCS program stipulates that as long as the driver has applied the brakes the CCS program must never transition to the cruise mode. Also, in cases where the signal coming from the brake subsystem is corrupted then it is not safe for the program to transitions to the cruise mode. Finally, the program must not transition to the cruise mode in cases where it is in an unknown mode. Hence, we represent the safety specification of the CCS program by the following transition predicate:

\[
S_{CCS} = ((Brake = \text{applied}) \land (Brake' = \text{applied}) \land (SysMode' = \text{cruise})) \lor \\
((Brake = \text{unknown}) \land (SysMode' = \text{cruise})) \lor \\
((SysMode = \text{unknown}) \land (SysMode' = \text{cruise}))
\]

DiConic calculation of the fault-span and offending states. We instantiate two forward reachability nodes corresponding to the fault actions *F*₁ and *F*₂ and nine forward reachability nodes corresponding to program actions *A*₁-*A*₉. The state predicates computed by the reachability nodes of *F*₁ and *F*₂ are as follows:

- **Action** *F*₁. This action may set the *Brake* to an unknown value, thereby falsifying the state predicate \((SysMode \neq \text{unknown}) \land (Brake \neq \text{unknown})\). However, *F*₁ does not violate the closure of *I*₁. Therefore, the program may be perturbed to *I*₁ by *F*₁.

- **Action** *F*₂. The execution of the fault action *F*₂ violates the closure of both state predicates *I*₁ and \((SysMode \neq \text{unknown}) \land (Brake \neq \text{unknown})\).

Since the invariant is closed in program actions, in the first round of the forward reachability the set of reachable states would be equal to \(FS_{CCS} = *I*₁ \lor (SysMode = \text{unknown}) \lor (Brake = \text{unknown})\). Subsequent iterations of forward reachability would yield the same predicate \(FS_{CCS}\) as the reachable state predicate from \(FS_{CCS}\) by fault and program actions.
This is because if only \((\text{SysMode} = \text{unknown})\) holds, then no program actions is enabled, thereby no new states are reached. If only \((\text{Brake} = \text{unknown})\) holds, then \(\mathcal{I}_1\) is the set of reachable states from \(\mathcal{F}S_{\text{CCS}}\). For this reason, the fault-span of the CCS program is \(\mathcal{F}S_{\text{CCS}}\). Since fault actions do not directly violate the safety of specification, the base set of states for backward reachability is empty. Therefore, the set of offending states is empty.

**Removing the set of offending transitions.** We create nine synthesis nodes corresponding to the actions \(A_1 - A_9\). Since the only actions that cause the CCS program to transition to the cruise mode are actions \(A_3\) and \(A_9\), the only actions that may directly violate safety would be \(A_3\) and \(A_9\). Thus, only the corresponding synthesis nodes of these actions perform revisions and the rest of the actions remain unchanged in the failsafe program. We present the revised actions \(A_3\) and \(A_9\) as follows:

- **Action** \(A_3\). Step 3 of the corresponding synthesis node calculates the transition predicate \(((\text{Brake} = \text{applied}) \land (\text{Brake}' = \text{applied})) \lor (\text{Brake} = \text{unknown}) \land (\text{SysMode}' = \text{cruise})\) as the set of transitions that violate the safety specification and should be excluded from action \(A_3\). Therefore, action \(A_3\) would be revised as follows:

\[
A_3 : ((\text{SysMode} = \text{inactive}) \land (\text{Lever} = \text{constant}) \land (\text{Ignition} = \text{on}) \land (\text{EngState} = \text{running}) \land (\text{Brake} = \text{notApplied})) \rightarrow \text{SysMode} := \text{cruise};
\]

- **Action** \(A_9\). For a similar reason, the synthesis node corresponding to the action \(A_9\) returns the following revised action:

\[
A_9 : ((\text{SysMode} = \text{override}) \land (\text{Ignition} = \text{on}) \land (\text{EngState} = \text{running}) \land (\text{Brake} = \text{notApplied}) \land ((\text{Lever} = \text{constant}) \lor (\text{Lever} = \text{resume}))) \rightarrow \text{SysMode} := \text{cruise};
\]

Since the set of offending states is empty, no state is removed from the invariant. Therefore, the invariant of the failsafe program is equal to \(\mathcal{I}_{\text{CCS}}\). We would like to emphasize that our DiConic approach significantly simplifies the addition of failsafe fault-tolerance by focusing on each of the above nine actions separately instead of adding fault-tolerance to all of them at once.
6.3 Token Ring

In this section, we synthesize a token ring program that is failsafe fault-tolerant to process restart faults. The fault-intolerant Token Ring (TR) program consists of four processes $P_0, P_1, P_2,$ and $P_3$ arranged in a ring. Each process $P_i$, $0 \leq i \leq 3$, has a variable $x_i$ with the domain $\{-1, 0, 1\}$. We say that process $P_i$, $1 \leq i \leq 3$, has the token if and only if $(x_i \neq x_{i-1})$ and fault transitions have not corrupted $P_i$ and $P_{i-1}$. And, $P_0$ has the token if $(x_3 = x_0)$ and fault transitions have not corrupted $P_0$ and $P_3$. Process $P_i$, $1 \leq i \leq 3$, copies $x_{i-1}$ to $x_i$ if the value of $x_i$ is different from $x_{i-1}$. This action passes the token to the next process. Also, if $(x_0 = x_3)$ holds then process $P_0$ copies the value of $(x_3 + 1) \mod 2$ to $x_0$. Thus, if we initialize every $x_i$, $0 \leq i \leq 3$, with 0, then process $P_0$ has the token and the token circulates along the ring. We specify the action of $P_0$ as follows.

$$A_0: \quad (x_0 = x_3) \quad \rightarrow \quad x_0 := (x_3 + 1) \mod 2;$$

Since processes $P_1, P_2,$ and $P_3$ are similar, we present their actions in a parameterized format, where $1 \leq i \leq 3$.

$$A_i: \quad (x_i \neq x_{i-1}) \quad \rightarrow \quad x_i := x_{i-1};$$

Read/Write restrictions. Each process $P_i$, $1 \leq i \leq 3$, is only allowed to read $x_{i-1}$ and $x_i$, and allowed to write $x_i$. Process $P_0$ is allowed to read $x_3$ and $x_0$, and write $x_0$.

State-corruption faults. The faults may corrupt the value of a process if that process and its predecessor (i.e., its locality) are not already corrupted. We model the effect of faults on a process $P_i$ by setting $x_i = -1$. Thus, the fault actions are as follows:

$$F_0: \quad (x_0 \neq -1) \land (x_3 \neq -1) \quad \rightarrow \quad x_0 := -1;$$
$$F_1: \quad (x_1 \neq -1) \land (x_0 \neq -1) \quad \rightarrow \quad x_1 := -1;$$
$$F_2: \quad (x_2 \neq -1) \land (x_1 \neq -1) \quad \rightarrow \quad x_2 := -1;$$
$$F_3: \quad (x_3 \neq -1) \land (x_2 \neq -1) \quad \rightarrow \quad x_3 := -1;$$

Note that there exist no read/write restrictions for the fault actions because we assume that fault actions can read and write arbitrary program variables.
Safety specification. Based on the problem specification, the fault-tolerant program is not allowed to take a transition where a non-corrupted process copies a corrupted value from its predecessor.

\[
S_{TR} : \begin{cases} 
(x_0 = -1) \land (x_1 \neq -1) \land (x'_1 = -1) \\
(x_1 = -1) \land (x_2 \neq -1) \land (x'_2 = -1) \\
(x_2 = -1) \land (x_3 \neq -1) \land (x'_3 = -1) \\
(x_3 = -1) \land (x_0 \neq x'_0) 
\end{cases}
\]

Invariant. The invariant of the program consists of the states where no process is corrupted and there exists only one token in the ring. The state predicate \(I_{TR}\) represents the invariant of the token ring program, where

\[
I_{TR} : \begin{cases} 
(x_0 = 0) \land (x_1 = 0) \land (x_2 = 0) \land (x_2 = 0) \\
(x_0 = 1) \land (x_1 = 0) \land (x_2 = 0) \land (x_2 = 0) \\
(x_0 = 1) \land (x_1 = 1) \land (x_2 = 0) \land (x_2 = 0) \\
(x_0 = 1) \land (x_1 = 1) \land (x_2 = 1) \land (x_2 = 0) \\
(x_0 = 1) \land (x_1 = 1) \land (x_2 = 1) \land (x_2 = 1) \\
(x_0 = 0) \land (x_1 = 1) \land (x_2 = 1) \land (x_2 = 1) \\
(x_0 = 0) \land (x_1 = 0) \land (x_2 = 1) \land (x_2 = 1) \\
(x_0 = 0) \land (x_1 = 0) \land (x_2 = 0) \land (x_2 = 1) 
\end{cases}
\]

DiConic calculation of the fault-span and offending states. In DiConic forward reachability on fault actions, in the first iteration, the fault action \(F_0\) reaches the state predicate \(RS_0\) from the invariant \(I_{TR}\), where \(RS_0 \equiv ((x'_0 = -1) \land (((x'_1 = 0) \land (x'_2 = 0)) \lor ((x'_2 = 1) \land (x'_3 = 1)) \lor ((x'_1 = 1) \land (x'_3 = 0))))\) from the invariant \(I_{TR}\). Likewise, the reachability nodes corresponding to \(F_1, F_2\) and \(F_3\) respectively send the state predicate \(RS_1, RS_2,\) and \(RS_3\) to the reachability coordinator, where

\[
RS_1 \equiv (x'_1 = -1) \land \\
((x'_0 = 0) \land (x'_2 = 0)) \lor ((x'_2 = 1) \land (x'_3 = 1)) \lor ((x'_0 = 1) \land (x'_3 = 0)), \\
RS_2 \equiv (x'_2 = -1) \land \\
((x'_0 = 0) \land (x'_1 = 0)) \lor ((x'_1 = 1) \land (x'_3 = 1)) \lor ((x'_0 = 1) \land (x'_3 = 0)),\text{ and} \\
RS_3 \equiv (x'_3 = -1) \land \\
((x'_0 = 0) \land (x'_1 = 0)) \lor ((x'_1 = 1) \land (x'_2 = 1)) \lor ((x'_0 = 1) \land (x'_2 = 0)).
\]

At the end of the first round of the forward reachability computation, the reachability coordinator computes the state predicate \(reachedStates\) (see Figure 3), which is equal to

31
Note that, in the first round of forward reachability, the execution of program actions from the invariant $I_{TR}$ does not yield states outside the invariant. In the second round, the actions of the fault-intolerant program that start in a state in reachedStates may propagate the corrupted value and result in states in which more than one process is corrupted. Thus, all possible states in the state space may be reached due to the occurrence of faults and execution of program actions outside the invariant. Therefore, the fault-span of the token ring program for fault actions $F_0-F_3$ from the invariant $I_{TR}$ is equal to true (i.e., the universal set). Since in this case fault actions do not directly violate safety specification, the base set of states for backward reachability is empty. Therefore, the set of offending states is empty.

**Removing the set of offending transitions.** We create four synthesis nodes corresponding to the actions of $A_0-A_3$. Since the set of offending states is empty, Steps 1 and 2 in SynthesisNode (see Figure 4) do not result in the exclusion of any transitions. Nonetheless, program actions violate the safety of specification when they propagate a corrupted value outside the invariant. The synthesis nodes eliminate such transitions in Steps 3 and 4, thereby revising program actions as follows:

- **Action $A_0$.** Step 3 calculates the transition predicate $(x_3 = -1) \land (x_0 = x_3) \land (x'_0 = 0)$ as the set of transitions that violate the safety specification and should be excluded from action $A_0$. Therefore, the revised action $A_0$ is as follows:

  
  \[(x_0 = x_3) \land (x_3 \neq -1) \quad \longrightarrow \quad x_0 := (x_3 + 1) \mod 2;\]

- **Actions $A_1$-$A_3$.** We present the revised actions $A_1$-$A_3$ as follows, for $1 \leq i \leq 3$:

  
  \[(x_i \neq x_{i-1}) \land (x_{i-1} \neq -1) \quad \longrightarrow \quad x_i := x_{i-1};\]

Since the set of offending states is empty, no state is removed from the invariant. Therefore, the invariant of the failsafe program is equal to $I_{TR}$. 

RS_0 \lor RS_1 \lor RS_2 \lor RS_3$. 

7 Related Work

In this section, we discuss related work on existing divide-and-conquer synthesis methods [25, 26] and techniques for reducing the time/space complexity of automatic addition of fault-tolerance [11, 13, 17, 23, 27]. Specifically, Smith [25] presents a divide-and-conquer approach for synthesizing programs from their algebraic specifications, where he decomposes the program specification into the specifications of sub-problems and combines the results of synthesizing solutions for sub-problems. Puri and Gu [26] propose a divide-and-conquer synthesis method for asynchronous digital circuits, where they decompose circuit specifications and satisfy design constraints for each sub-specification. While the aforementioned approaches inspire our work, they are essentially specification-based approaches and do not directly focus on adding failsafe fault-tolerance to existing programs.

Previous work on automatic addition of fault-tolerance [11, 13, 17, 23, 27] mostly focuses on techniques for reducing time/space complexity of synthesis. For example, Kulkarni et al. [17] present a set of heuristics based on which they reduce the time complexity of adding fault-tolerance to integrated models of distributed programs. Kulkarni and Ebnesasir [11] present a technique for reusing the computations of an existing fault-tolerant program in order to enhance its level of tolerance. They also present a set of pre-synthesized fault-tolerance components [27] that can be reused during the addition of fault-tolerance to different programs. We have presented a SAT-based technique [23] where we employ SAT solvers to solve some verification problems during the addition of fault-tolerance to integrated program models. Bonakdarpour and Kulkarni [13] present a symbolic implementation of the heuristics in [17] where they use BDDs to model distributed programs.

Our DiConic approach significantly differs from the previous work in that we present a new paradigm for decomposing the problem of adding failsafe fault-tolerance instead of adding failsafe fault-tolerance to an integrated combinatorial model of the entire program. More specifically, our DiConic approach is orthogonal to time/space complexity issues since one can benefit from existing techniques to mitigate the time/space complexity of revising individual program actions. While we have used the Yices SMT solver to implement our
DiConic approach, the distributed nature of our algorithm enables us to implement different techniques and data structures for the revision of different program actions depending on their granularity (e.g., single variable updates, nested iterative instructions, etc.).

8 Conclusions and Future Work

We presented a divide-and-conquer approach, called DiConic, for the addition of failsafe fault-tolerance to (distributed) programs, where in the presence of faults a failsafe program guarantees to satisfy at least its safety specification. We specifically focused on the following question: Given a fault-intolerant program and a specific fault-type, how can we revise each program action separately so that the entire program becomes failsafe fault-tolerant? To address this question, we decomposed the problem of adding failsafe fault-tolerance into sub-problems. In each sub-problem, we concentrated on one program action and determined how that action should be revised so that the entire program would be failsafe fault-tolerant. We validated our approach for the classic problem of Byzantine Generals problem and for a simplified version of an altitude switch controller.

As an extension of this work, we are investigating the DiConic addition of recovery to programs, where we revise program instructions in isolation so that the entire program would eventually recover to its invariant after faults stop occurring. Another extension of this work is to enhance the efficiency of the synthesis coordinator by developing its distributed version. DiConic addition of fault-tolerance is a special case of a more general problem in which new Temporal Logic [28] properties are incrementally added to an existing program (as defined and addressed in our previous work [29]). Towards this end, we plan to develop new DiConic algorithms for automatic addition of new properties to (concurrent and distributed) programs.

Appendix A: The Yices Specifications

In this section, we illustrate how we employ the Yices SMT solver to apply the algorithms *Synthesis_Node* and *Synthesis_Coordinator* (see Figures 4 and 5) to each case study presented in Section 6. Specifically, for each case study, we define a logical context that specifies a static structure for the fault-intolerant program based on the program and fault actions. The synthesis coordinator distributes a copy of this logical context to each synthesis node. A synthesis node uses this context to interact with an instance of the Yices SMT solver (running locally) towards revising its associated action. In Subsection A.1, we present the Yices specification of the Byzantine Generals problem and the assertions used to verify the conditions in algorithms *Synthesis_Node* and *Synthesis_Coordinator*. Then, in Subsection A.2, we demonstrate how to add failsafe fault-tolerance to the altitude switch program. Subsequently, in Subsection A.3, we present the Yices specification of the cruise control system. Finally, in Subsection A.4, we discuss the specification of the token ring program.

Appendix A.1: Byzantine Generals Problem

In this section, we present the logical context in which we specified the Byzantine Generals problem.
